Structural and functional aspects of the human globin genes. A number of studies have been done using recombinant DNAs and protein-binding assays to investigate the cis-acting sequences and trans-acting factors involved in the regulation of human alpha and beta globin genes. However, most of these are indirect and describe the interactions between the globin genes and various regulatory sequences within the genes themselves. A few studies have begun to characterize direct effects of DNA sequences within globin genes, and some of these studies suggest that there may be several levels of regulation, each affected by a particular DNA sequence. To date, there have been no studies that have directly correlated DNA-sequence effects with changes in the expression of globin genes. Because of the complexity of the sequences within globin genes and the multiplicity of levels of regulation, the direct assays of gene expression described in this study may be useful in providing insights into the ways in which multiple levels of regulation act to control the levels of expression of human globin genes.
